2 Introduction

Debugging Rust code on embedded system today is not a very good experience for many reasons. One of the big problems is debugging optimized code is often near impossible. That is because the compilers today are very good at inlining the code and removing unused code. This changes the program so drastically in many cases that when trying to debug the code all the original variable can be optimized out. Thus the user doesn't get any useful information from the debugger about the program which makes is near impossible to debug. One of the big reasons why variable gets optimized out is because unoptimized code always push the value of the variable to memory which then can be read by the debugger at anytime. This is not done for optimized code because speed is prioritized and storing the value of a variable that will not be used on the stack is costly. Thus the time that most variable exist is very short in optimized code which results in that the debugger saying that a variable is optimized out.

2.1 Background

TODO

2.2 Motivation

The main motivation is that optimized Rust code can be up to 100 times faster then unoptimised code. That is a very large difference in speed compared to other languages like C for example, were the optimized code is about 2-4 times faster then the unoptimized code. Thus for language like C it is much more acceptable to not be able to debug optimized code because the different isn't that large compared to Rust. But in the case of Rust code the different is so large that some programs are to slow to run without optimization. This causes the problem that the code can't be debugged because debuggers don't work well on optimized code and unoptimized code is to slow to run. Because of that there is a need for debuggers that can give enough information to debug optimized Rust code. Then there is also the argument that relying only on testing the optimized code instead of going through and checking that is is correct is bad. The reason being that there can be extremely many paths that needs to be tested and it is sometimes not feasible to test all of them. In these cases it is less costly to verify that the code is correct then to test every path.

Another large motivation for this thesis is that the most common way of debugging Rust code on embedded systems is complicated for a beginner. One of the reason being that it requires two programs being openocd and gdb, it also requires configuration files which takes some time to understand and configure. This is not very accessible for people that have no experience with these programs and is unnecessarily complicated. The ideal solution for accessibility would be to have a single program instead of two and that it requires less configuring, thus making it as easy as possible for a new person to debug there code.

Most of the debuggers used for *Rust* code are written in other programming languages and there isn't a lot of debugging tools written in *Rust* yet. Thus one of the motivation for the thesis debugger to be written in *Rust* is to contribute with a example of a debugger written in *Rust* to the *Rust* community. This also relates back to improving debugging for optimized *Rust* code because that is a large and hard problem that requires a lot of work to solve and to maintain the solution. One of the most realistic way that will happen is if the *Rust* community around debugging grows and more people contribute with there solutions and ideas.

Another way this thesis contributes to the *Rust* community is by making a library that simplifies the process of retrieving information form the debug information. This is important because it makes retrieving debug information simpler for new developers to start contributing to the *Rust* debug community. Which will hopefully lead to better debugging for optimized *Rust* code.

There is also a economical reason wanting to have debuggers that work well for optimized code. As mentioned before testing all the paths in a program is sometimes not feasible because of the amount of work needed. But verifying that the program is correct and that the implementation is correct is another way to ensure that the program works as intended. It is even sometimes the preferred solution because then the program is proven to work correctly. And a debugger is one of the vital tools needed for confirming that a implementation is correct. Verifying the correctness of a program and the implementation can also be cheaper then testing in those cases where the programs has extremely many paths. Thus improving the tools needed to verify the correctness of the implementation can intern reduce the cost of verifying that the program works as intended. And it can even reduce the amount of money witch companies spend on testing there code. The amount of money spent on testing of code each year is about xxx and thus the potential savings on testing us huge.

2.3 Problem definition

There are two main problem that this thesis tries to tackle to improve the experience of debugging optimized code for embedded systems. The fist problem is about the generation of the debug information, if more debug information can be generated then there is more information the debugger can retrieve an show the user. This is also were the problem starts with debugging optimized code, because debuggers needs the debug information to understand the relation between the source code and the machine code. Thus it is very important that the compiler generates as much debug information as possible, because there is nothing that can be done later to get more information. The first problem then is to look at the different options that can be set in the *llvm* compiler to improve the generations of debug information without impacting the optimisation of the code to much. Speed of the resulting code is still a big priority.

The second problem is looking at the available debug information that the *llvm* compiler generates for optimized code and creating a debugger that utilises that information to the fullest. This problem has two parts to it, the first being

retrieving the needed information from the debug information. This will be the hardest part and is the most important for improving the debugging for optimized code. The second part is to display the debug information to the user in a user friendly way.

The goal of solving these to problems is to create a debugger that gives a better debugging experience for optimized rust code on embedded systems then some of the most commonly used debugger, such as gdb and lldb. And to inspire further development for debugging tools in the rust community.

2.6 Delimitations

As mentioned one of the main problems for getting a debugger to work for optimized code is getting the compiler to generate all the debug information needed. In the case of the Rust compiler it is the LLVM library that handles the debug information generation. LLVM is a very lager project that many people are working on and thus it would be to much work for this thesis to try and improve the debug information generation. Thus this thesis is limited in solving this problem by the current functionality of LLVM.

The compiler backend LLVM that the Rust compiler uses supports two debugging file formats that holds all the debug information. One of them is the DWARF format that has been around for a long time and is supported by many compilers and debuggers. The other one is CodeView format which is developed by Microsoft and has also been around for a long time. To make a debugger that supports both formats would be a lot of extra work that doesn't contribute to solving the main problem of this thesis. Thus it has been decided to only support the DWARF format because it has good documentation and a opensource community around it.

The scope of this thesis also dose not include changing or adding to the DWARF format standard. The main reason is that it takes years for a new version of the standard to be released and thus there is not enough time for this thesis to see and realise that change or addition. Another reason is that even if a new version of the DWARF format could be release in the span of this thesis, it would take years before the Rust compiler had been updated to use the new standard. Currently the newest DWARF version is 5 but the Rust compiler still uses the DWARF 4 format.

Many of the debuggers today have a lot of functionality to help the user understand what is happening in the program that they are debugging. An example of these functionality are debuggers that support the ability to go backwards in the program. Functionalities like this are useful but not contributing much to the main problem of debugging optimized code. Which is that most of the source code variables get optimized away and thus making it extremely hard to understand what is happening in the code. So to keep this thesis focused on the main problem the feature the debugger will have is restricted to evaluating stack frames and the variables present in each frame, the ability to add and remove breakpoints. And the ability to control the program by stopping, continuing and stepping an instruction.

When debugging code on embedded systems the debugger needs to know a lot about the hardware the code is running on. It has to know the size of the memory and the number of registers, it also has to know which are the special registers such as the program counter register and more. There is also the endianity of the values store on in memory and registers so the debugger can convert it to the correct type. Then there is also the type of machine code the processes uses and the instruction mode use. To support all the different microcontroller would be to much work for this thesis. Thus the debugger is limited to work with the Nucleo-64 STM32F401 card because it is the one that is available. And it will only support the instruction set Thumb mode made by arm. The debugger will be design to work with other similar microcontroller but to test and grantee that it will work with them is to much work for this thesis.

Another part of this thesis is the interaction between the user and the debugger. Existing debugger like gdb both have a CLI and a GUI, thus it is up to the user which one they want to use. From a usability perspective the debugger in this thesis should also have both of the option for the user to choose from. A CLI is not that much work to implement but a GUI takes a lot of work to implement. Luckily Microsoft has made a protocol for debuggers that specifies an adapter that handles the communication between the GUI and the debugger. This protocol is called DAP and is used by VSCode. Thus the scope of the debugger will include implementing the DAP protocol and an extension for VSCode.

The DWARF format is very extensive and supports a lot of different program languages, the specifications for the different languages are a little different form each other. Because this thesis is about Rust code the thesis will only go into detail in how to read the DWARF format for Rust. The specification for the DWARF format is also very good at explaining how the information is structured. Thus a this thesis will not go into all the detail in how to read the DWARF format instead it will focus on explaining how the information in the DWARF format can be used in combination to get important information that the user wants.
